

NCP1205

Single Ended PWM Controller Featuring QR Operation and Soft Frequency Foldback

The NCP1205 combines a true Current Mode Control modulator and a demagnetization detector to ensure full Discontinuous Conduction Mode in any load/line conditions and minimum drain voltage switching (Quasi-Resonant operation, also called critical conduction operation). With its inherent Variable Frequency Mode (VFM), the controller decreases its operating frequency at constant peak current whenever the output power demand diminishes. Associated with automatic multiple valley switching, this unique architecture guarantees minimum switching losses and the lowest power drawn from the mains when operating at no-load conditions. Thus, the NCP1205 is optimal for applications targeting the newest International Energy Agency (IEA) recommendations for standby power.

The internal High-Voltage current source provides a reliable charging path for the V_{CC} capacitor and ensures a clean and short start-up sequence without deteriorating the efficiency once off.

The continuous feedback signal monitoring implemented with an Over-Current fault Protection circuitry (OCP) makes the final design rugged and reliable. An internal Over Voltage Protection (OVP) circuit continuously monitors the V_{CC} pin and stops the IC whenever its level exceeds 36 V. The DIP14 offers an adjustable version of the OVP threshold via an external resistive network.

Features

- Natural Drain Valley Switching for Lower EMI and Quasi-Resonant Operation (QR)
- Smooth Frequency Foldback for Low Standby and Minimum Ripple at Light-Load
- Adjustable Maximum Switching Frequency
- Internal 200 ns Leading Edge Blanking on Current Sense
- 250 mA Sink and Source Driver
- Wide Operating Voltages: 8.0 to 36 V
- Wide UVLO Levels: 7.2 to 15 V Typical
- Auto-Recovery Internal Short-Circuit Protection (OCP)
- Integrated 3.0 mA Typ. Start-Up Source
- Current Mode Control
- Adjustable Over-Voltage Level
- Available in DIP8 and DIP14 Package

Applications

- High Power AC/DC Adapters for Notebooks, etc.
- Offline Battery Chargers
- Power Supplies for DVD, CD Players, TVs, Set-Top Boxes, etc.
- Auxiliary Power Supplies (USB, Appliances, etc.)

PIN CONNECTIONS

PIN FUNCTION DESCRIPTION

Pin No.		Pin Name	Function	Description
DIP8	DIP14			
1	1	HV	Start-up rail	Connected to the rectified HV rail, this pin provides a charging path to V _{CC} bulk capacitor.
2	3	Demag	Zero primary-current detection	This pin ensures the re-start of the main switcher when operating in free-run.
3	4	FB	Feedback signal to control the PWM	This level modulates the peak current level in free-running operation and modulates the frequency in VFM operation.
4	5	Ct	Timing capacitor	By adding a capacitor from Ct to the ground, the user selects the minimum/maximum operating frequency.
5	10	Gnd	The IC's ground	–
NA	6	OVP	Overshoot input	By applying a 2.8 V typical level on this pin, the IC is permanently latched-off until V _{CC} falls below UVLO _L .
6	11	Isense	The primary-current sensing pin	This pin senses the primary current via an external shunt resistor.
7	12	Drv	This pin drives the external switcher	The IC is able to deliver or absorb 250 mA peak currents while delivering a clamped driving signal.
8	13	V _{CC}	Powers the IC	A positive voltage up to 40 V <i>typical</i> can be applied upon this pin before the IC stops.

1. DIP14 has different pinouts. Please see Pin Connections.
2. Pin 2, 7, 8, 9 and 14 are nonconnected on DIP14.

APPLICATION INFORMATION

Introduction

By implementing a unique smooth frequency reduction technique, the NCP1205 represents a major leap toward low-power Switch-Mode Power Supply (SMPS) integrated management. The circuit combines free-running operation with minimum drain-source switching (so-called valley switching), which naturally reduces the peak current stress as well as the ElectroMagnetic Interferences (EMI). At

nominal output power, the circuit implements a traditional current-mode SMPS whose peak current setpoint is given by the feedback signal. However, rather than keeping the switching frequency constant, each cycle is initiated by the end of the primary demagnetization. The system therefore operates at the boundary between Discontinuous Conduction Mode (DCM) and Continuous Conduction Mode (CCM). Figure 11 details this terminology:

Figure 11. Defining the Conduction Mode, Discontinuous, Continuous and Borderline

When the output power demands decreases, the natural switching frequency raises. As a natural result, switching losses also increase and degrade the SMPS efficiency. To overcome this problem, the maximum switching frequency of the NCP1205 is clamped to typically 125 kHz. When the free running mode (also called Borderline Control Mode, BCM) reaches this clamp value, an internal Voltage-Controlled Oscillator (VCO) takes over and starts to decrease the switching frequency: we are in Variable Frequency Mode (VFM). Please note that during this transition phase, the peak current is not fixed but is still decreasing because the output power demand does. At a given state, the peak current reaches a minimum ceil (typically 250 mV/Rsense), and cannot go further down: the switching frequency continues its decrease down to a possible minimum of 0 Hz (the IC simply stops switching). During normal free-running operation and VFM, the controller always ensures single or multiple drain-source

valley switching. We will see later on how this is internally implemented.

The FLYBACK operation is mainly defined through a simple formula:

$$P_{out} = \frac{1}{2} \cdot L_p \cdot I_p^2 \cdot F_{sw} \quad (eq. 1)$$

With:

Lp the primary transformer inductance (also called the magnetizing inductance)

Ip the peak current at which the MOSFET is turned off

Fsw the nominal switching frequency

To adjust the transmitted power, the PWM controller can play on the switching frequency or the peak current setpoint. To refine the control, the NCP1205 offers the ability to play on both parameters either altogether on an individual basis.

In order to clarify the device behavior, we can distinguish the following *simplified* operating phases:

1. The load is at its nominal value. The SMPS operates in borderline conduction mode and the switching frequency is imposed by the external elements (V_{in} , L_p , I_p , V_{out}). The MOSFET is turned on at the minimum drain–source level.
2. The load starts to decrease and the free–running frequency hits the internal clamp.
3. The frequency can no longer naturally increase because of the clamp. The frequency is now controlled by the internal VCO but remains constant. The peak current finds no other option that diminishing to satisfy equation (1).
4. The peak current has reached the internal minimum ceiling level and is now frozen for the remaining cycles.
5. To further reduce the transmitted power (V_{FB} goes up), the VCO decreases the switching frequency. In case of output overshoot, the VCO could decrease the frequency down to zero. When the overshoot has gone, V_{FB} diminishes again and the IC smoothly resumes its operation.

Advantages of the Method

By implementing the aforementioned control scheme, the NCP1205 brings the following advantages:

- Discontinuous only operation: in DCM, the Flyback is a first order system (at low frequencies) and thus naturally eases the feedback loop compensation.
- A low–cost secondary rectifier can be used due to smooth turn–off conditions.
- Valley switching ensures minimum switching losses brought by C_{oss} and all the parasitic capacitances.
- By folding back the switching frequency, you turn the system into Pulse Duration Modulation. This method prevents from generating *uncontrolled* output ripple as with hysteretic controllers.
- By letting you control the peak current value at which the frequency goes down, you ensure that this level is low enough to avoid transformer acoustic noise generation even at audible frequencies.

Detailed Description

The following sections describe the internal behavior of the NCP1205.

Free–Running Operation

As previously said, the operating frequency at nominal load is dictated by the external elements. We can split the different switching sections in two separated instants. In the following text we use the internal error voltage, V_{err} . This level is elaborated as Figure 14 portrays. V_{err} is linked to V_{FB} (pin 4) by the following formula:

$$V_{err} = 10 - 3 \cdot V_{FB} \quad (\text{eq. 2})$$

ON time: The ON time is given by the time it takes to reach the peak current setpoint imposed by the level on FB pin (pin 4). Since this level is internally divided by three, the peak setpoint is simply:

$$I_{pk} = \frac{1}{3 \cdot R_{sense}} \cdot V_{err} \quad (\text{eq. 3})$$

The rising slope of the peak current is also dependent on the inductance value and the rectified DC input voltage by:

$$\frac{dI_L}{dt} = \frac{V_{inDC}}{L_p} \quad (\text{eq. 4})$$

By combining both equations, we obtain the ON time definition:

$$t_{on} = \frac{L_p}{V_{inDC}} \cdot I_p = \frac{L_p \cdot V_{ERR}}{V_{inDC} \cdot 3 \cdot R_{sense}} \quad (\text{eq. 5})$$

OFF time: The time taken by the demagnetization of the transformer depends on the reset voltage applied at the switch opening. During the conduction time of the secondary diode, the primary side of the transformer undergoes a reflected voltage of: $[N_p/N_s \cdot (V_f + V_{out})]$. This voltage applied on the primary inductance dictates the time needed to decrease from I_p down to zero:

$$t_{off} = \frac{L_p}{\left[\frac{N_p}{N_s} \cdot (V_{out} + V_f) \right]} \cdot I_p = \frac{L_p \cdot V_{err}}{\left[\frac{N_p}{N_s} \cdot (V_{out} + V_f) \right] \cdot 3 \cdot R_{sense}} \quad (\text{eq. 6})$$

By adding $t_{on} + t_{off}$, we obtain the natural switching frequency of the SMPS operating in Borderline Conduction Mode (BCM):

$$t_{on} + t_{off} = \frac{V_{err} \cdot L_p}{3 \cdot R_{sense}} \cdot \left[\frac{1}{V_{inDC}} + \frac{1}{\left[\frac{N_p}{N_s} \cdot (V_{out} + V_f) \right]} \right] \quad (\text{eq. 7})$$

NCP1205

If we now enter this formula into a spreadsheet, we can easily plot the switching frequency versus the output power demand:

Figure 12. A Typical Behavior of Free Running Systems with a Smooth Frequency Foldback with the NCP1205

The typical above diagram shows how the frequency moves with the output power demand. The components used for the simulation were: $V_{in} = 300\text{ V}$, $L_p = 6.5\text{ mH}$, $V_{out} = 10\text{ V}$, $N_p/N_s = 12$.

The red line indicates where the maximum frequency is clamped. At this time, the VCO takes over and decreases the switching frequency to the minimum value.

VCO Operation

The VCO is controlled from the V_{err} voltage. For V_{err} levels above 1.0 V, the VCO frequency remains unchanged at 125 kHz. As soon as V_{err} starts to decrease below 1.0 V,

the VCO frequency decreases with a typical *small-signal* slope of -175 kHz/mV @ $V_{err} = 500\text{ mV}$ down to zero (typically at $FB \approx 3.3\text{ V}$). The demagnetization synchronization is however kept when the T_{off} expands. The maximum switching frequency can be altered by adjusting the C_t capacitor on pin 5. The 125 kHz maximum operation ensures that the fundamental component stays external from the international EMI CISPR-22 specification beginning.

The following drawing explains the philosophy behind the idea:

Figure 13. When the Power Demand goes Low, the Peak Current is Frozen and the Frequency Decreases

Zero Crossing Detector

To detect the zero primary current, we make use of an auxiliary winding. By coupling this winding to the primary, we have a voltage image of the flux activity in the core. Figure 13 details the shape of the signal in BCM.

The auxiliary winding for demagnetization needs to be wired in Forward mode. However, the application note describes an alternative solution showing how to wire the winding in Flyback as well. As Figure 13 depicts, when

the MOSFET closes, the auxiliary winding delivers $(N_{aux}/N_p \cdot V_{in})$. At the switch opening, we couple the auxiliary winding to the main output power winding and thus deliver: $(-N_{aux}/N_s \cdot V_{out})$. When DCM occurs, the ringing also takes place on the auxiliary winding. As soon as the level crosses-up the internal reference level (65 mV), a signal is internally sent to re-start the MOSFET. Three different conditions can occur:

1. In BCM, every time the 65 mV line is crossed, the switch is immediately turned-on. By accounting for the internal Demag pin capacitance (10–15 pF typical), you can introduce a fixed delay, which, combined to the propagation delay, allows to precisely re-start in the drain-source valley (minimum voltage to reduce capacitive losses).
2. When the IC enters VFM, the VCO delivers a pulse which is internally latched. As soon as the demagnetization pulse appears, the logic re-starts the MOSFET.
3. As can be seen from Figure 13, the parasitic oscillations on the drain are subject to a natural damping, mainly imputed to ohmic losses. At a given point, the demag activity on the auxiliary winding becomes too low to be detected. To avoid any re-start problem, the TY72001 features an internal 4.0 μ s timeout delay. This timeout runs after each demag pulse. If within 4.0 μ s further to a demag pulse no activity is detected, an internal signal is combined with the VCO to actually re-start the MOSFET (synchronized with Ct).

Error Amplifier and Fault Detection

The NCP1205 features an internal error amplifier solely used to detect an overcurrent problem. The application assumes that all the error gain associated with the precise reference level is located on the secondary side of the SMPS. Various solutions can be purposely implemented such as the TL431 or a dedicated circuit like the MC33341. In the NCP1205, the internal OPAMP is used to create a virtual ground permanently biased at 2.5 V (Figure 14), an internal reference level. By monitoring this virtual ground further called V(-), we have the possibility to confirm the good behavior of the loop. If by any mean the loop is broken (shorted optocoupler, open LED etc.) or the regulation cannot be reached (true output short-circuit), the OPAMP network is adjusted in order to no longer be able to ensure the 2.5 V virtual point V(-). If V(-) passes down the 1.5 V level (e.g. output shorted) for a time longer than 128 ms, then the pulses are stopped for 8 x 128 ms. The IC enters a kind of burst mode with bunch of pulses lasting 128 ms and repeating every 8 x 128 ms. If the loop is restored within the 8 x 128 ms period, then the pulses are back again on the output drive (synchronized with UVLO_H).

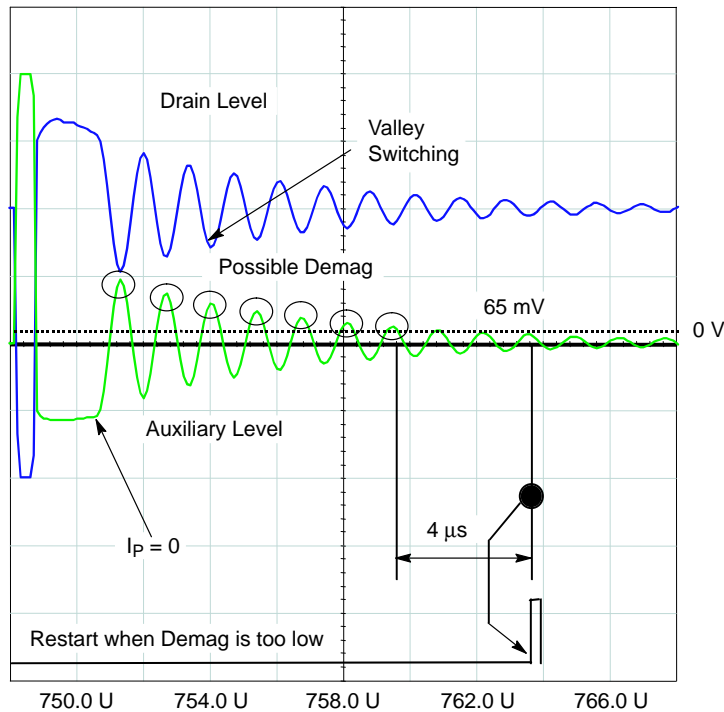

Figure 14. Core Reset Detection is done through an Auxiliary Winding Operated in Forward

NCP1205

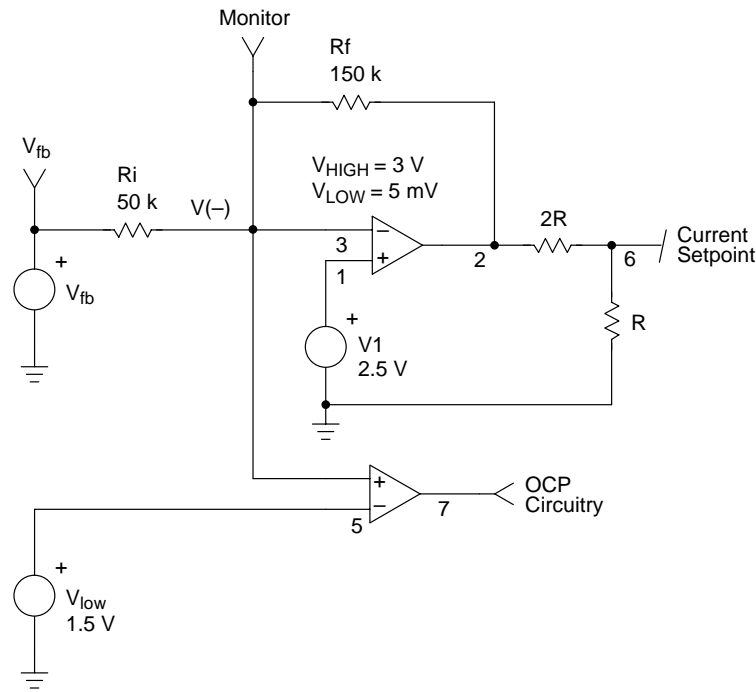

Figure 15. This Typical Arrangement Allows for an Easy Fault Detection Management

To illustrate how the system reacts to a variable FB level, we have entered the above circuit into a SPICE simulator and observed the output waveforms. When FB is within regulation, the error flag is low. However, as soon as FB leaves its normal operating area, the OPAMP can no longer keep the $V(-)$ point and either goes to the positive top or down to zero: the error flag goes high.

Because of the large amount of delay necessary for this 128 ms operation, the capacitor used for the timing is C_t ,

connected from ground to pin 5. In normal VFM operation, this timing capacitor serves as the VCO capacitor and the error management circuit is transparent. As soon as an error is detected (error flag goes high), an internal switch routes C_t to the 128 ms generator. As a first effect, the switching frequency is no longer controlled by the VCO (if the error appears during VFM) and the system is relaxed to natural BCM. The capacitor now ramps up and down to be further divided and finally create the 128 ms delay.

Figure 16. By Monitoring the Internal Virtual Ground, the System can Detect the Presence of a Fault

As soon as the system recovers from the error, e.g. FB is back within its regulation area, the IC operation comes back to normal.

To avoid any system thermal runaway, another internal 8 x 128 ms delay is combined with the previous 128 ms. It works as follows: the 128 ms delay is provided to account for any normal transients that engender a temporary loss of feedback (FB goes toward ground). However, when the 128 ms period is actually over (the feedback is definitively lost) the IC stops the output driving pulses for a typical period of 8 x 128 ms. During this mode, the rest of the functions are still activated. For instance, in lack of pulses, the self-supplied being no longer provided, the start-up source turns on and off (when reaching the corresponding UVLO_L and UVLO_H levels), creating an hiccup waveform on the V_{cc} line. As soon as the feedback condition is restored, the 8 x 128 ms is interrupted and, in synchronism with the V_{cc} line, the IC is back to normal. The following diagrams show how this mechanism takes place when FB is down to zero (optocoupler opened) or up to V_{cc} (optocoupler shorted). If we assume that the error is permanently present, then a burst mode takes place with a 128/8 x 128 = 12.5% duty-cycle. The real transmitted power is thus:

$$P_{outBURST} = \frac{1}{2} \cdot L_p \cdot I_p^2 \cdot F_{sw} \cdot DutyBURST$$

Overvoltage Detection (OVP)

OVP detection is done differently on the DIP8 and DIP14 versions. In the DIP8, because of available pin count, the OVP is accomplished by monitoring the V_{cc} voltage. On the DIP14, the device also monitors the V_{cc} level but in parallel, the triggering point has been pin-out to allow precise OVP selection. This pin can also be used to externally latch-off the IC.

As mentioned, Over Voltage Conditions are detected by monitoring the V_{cc} level. Figure 17 describes how three 10 V zener plus one 5.0 V zener are connected in series together with a 18 kΩ to ground. As soon as V_{cc} exceeds 40 V typical, a current starts to flow in the 18 k resistor. When the voltage developed across this element exceeds 2.8 V, an error is triggered and immediately latches the IC off. In lack of switching pulses, the V_{cc} capacitor is no longer refreshed by the auxiliary supply and slowly

discharges toward ground. When the V_{cc} level crosses UVLO_L, a new startup sequence occurs. If the OVP has gone, normal IC operation takes place. For different OVP levels, the comparator input is accessible through pin 6 in the DIP14 option.

Figure 17. In the DIP8 Version, the OVP Pad is not Pinned Out and is Available with DIP14 Devices Only

Protecting Pin 1 Against Negative Spikes

As any CMOS controller, NCP1205 is sensitive to negative voltages that could appear on its pins. To avoid any adverse latch-up of the IC, we strongly recommend inserting a 15 k resistor in series with pin 1 and the high-voltage rail, as shown in Figures 18 and 19. This 15 k resistor prevents from adversely latching the controller in case of negative spikes appearing on the bulk capacitor during the power-off sequence. Please note that this resistor does not dissipate any continuous power and can therefore be of low power type. Two 8.2 k can also be wired in series to sustain the large DC voltage present on the bulk.

Notes

Notes

ON Semiconductor and  are registered trademarks of Semiconductor Components Industries, LLC (SCILLC). SCILLC reserves the right to make changes without further notice to any products herein. SCILLC makes no warranty, representation or guarantee regarding the suitability of its products for any particular purpose, nor does SCILLC assume any liability arising out of the application or use of any product or circuit, and specifically disclaims any and all liability, including without limitation special, consequential or incidental damages. "Typical" parameters which may be provided in SCILLC data sheets and/or specifications can and do vary in different applications and actual performance may vary over time. All operating parameters, including "Typicals" must be validated for each customer application by customer's technical experts. SCILLC does not convey any license under its patent rights nor the rights of others. SCILLC products are not designed, intended, or authorized for use as components in systems intended for surgical implant into the body, or other applications intended to support or sustain life, or for any other application in which the failure of the SCILLC product could create a situation where personal injury or death may occur. Should Buyer purchase or use SCILLC products for any such unintended or unauthorized application, Buyer shall indemnify and hold SCILLC and its officers, employees, subsidiaries, affiliates, and distributors harmless against all claims, costs, damages, and expenses, and reasonable attorney fees arising out of, directly or indirectly, any claim of personal injury or death associated with such unintended or unauthorized use, even if such claim alleges that SCILLC was negligent regarding the design or manufacture of the part. SCILLC is an Equal Opportunity/Affirmative Action Employer.

PUBLICATION ORDERING INFORMATION

Literature Fulfillment:

Literature Distribution Center for ON Semiconductor
P.O. Box 5163, Denver, Colorado 80217 USA
Phone: 303-675-2175 or 800-344-3860 Toll Free USA/Canada
Fax: 303-675-2176 or 800-344-3867 Toll Free USA/Canada
Email: ONlit@hibbertco.com

N. American Technical Support: 800-282-9855 Toll Free USA/Canada

JAPAN: ON Semiconductor, Japan Customer Focus Center
4-32-1 Nishi-Gotanda, Shinagawa-ku, Tokyo, Japan 141-0031
Phone: 81-3-5740-2700
